## Current Biology

## Evolutionary History, Genomic Adaptation to Toxic Diet, and Extinction of the Carolina Parakeet

## Highlights

- First whole genome from the extinct Carolina parakeet and the sun parakeet
- Divergence time between Conuropsis and Aratinga around 3 mya
- Evidence for potential adaptation to toxic diet in two extremely conserved proteins
- No signs of inbreeding in the Carolina parakeet suggest the extinction was abrupt

## Authors

## In Brief

Gelabert et al. report the whole genome of the extinct Carolina parakeet and provide evidence of its phylogeny, adaptation to a toxic cocklebur diet, and demographic history. The lack of signs of recent inbreeding typically found in endangered species suggests its abrupt extinction was human mediated.

## SUMMARY

As the only endemic neotropical parrot to have recently lived in the northern hemisphere, the Carolina parakeet (Conuropsis carolinensis) was an iconic North American bird. The last surviving specimen died in the Cincinnati Zoo in 1918 [1]. The cause of its extinction remains contentious: besides excessive mortality associated to habitat destruction and active hunting, their survival could have been negatively affected by its range having become increasingly patchy [2] or by the exposure to poultry pathogens [3, 4]. In addition, the Carolina parakeet showed a predilection for cockleburs, an herbaceous plant that contains a powerful toxin, carboxyatractyloside, or CAT [5], which did not seem to affect them but made the birds notoriously toxic to most predators [3]. To explore the demographic history of this bird, we generated the complete genomic sequence of a preserved
specimen held in a private collection in Espinelves (Girona, Spain), as well as of a close extant relative, Aratinga solstitialis. We identified two non-synonymous genetic changes in two highly conserved proteins known to interact with CAT that could underlie a specific dietary adaptation to this toxin. Our genomic analyses did not reveal evidence of a dramatic past demographic decline in the Carolina parakeet; also, its genome did not exhibit the long runs of homozygosity that are signals of recent inbreeding and are typically found in endangered species. As such, our results suggest its extinction was an abrupt process and thus likely solely attributable to human causes.

## RESULTS

The Carolina Parakeet and the Sun Parakeet Genomes Given that de novo genome assembly is impractical with the typically short and degraded DNA found in historic and ancient

specimens [6, 7], we chose to generate a de novo assembly genome of the species' closest extant relative (Aratinga solstitialis; the sun parakeet), against which we could subsequently map and call full-genome variants from the sequenced Carolina parakeet (STAR Methods). Previous analyses of the phylogenetic relationship of the Conuropsis genus to extant parrots have been assessed based on morphology [8] and a short (876-nucleotide) fragment of the mtDNA genome retrieved from the toes of six specimens [9]. Both studies concluded that Conuropsis falls in a clade as a sister group to three Aratinga species [9]. Guided by this information, we generated a de novo reference genome of Aratinga solstitialis from a bird's breeder specimen. This genome was assembled and annotated using the B10K consortium pipelines [10] to render it consistent with previously published avian nuclear genomes during subsequent analyses. The genome was based on Illumina reads from three long-range Nextera libraries of different insert sizes and assembled with ALLPATH to a final N50 scaffold measure of 19.5 Mbp .

Following subsequent whole-genome shotgun sequencing of the Carolina parakeet DNA extract using the BGISeq-500 platform, which has been demonstrated to be effective for ancient DNA [11], we were able to map 209,887,920 unique reads from $C$. carolinensis against the $1,168,990,576$ bp of A. solstitialis genome, covering $93 \%$ of the genomic positions, with a mean depth of $13.4 \times$ (STAR Methods). We also recovered the entire mtDNA genome to $150 \times$ depth of coverage. The reads exhibit characteristic ancient DNA deamination pattern at their ends [12], with a value close to $5 \%$ (Figure S1) that is consistent with our sample being just 100 years old [13]. We determined which positions were derived in $C$. carolinensis or $A$. solstitialis using the chicken G. gallus as outgroup. A total of 28,348 missense and 152 nonsense mutations were identified between Conuropsis and Aratinga. Of the former, 502 mutations were predicted to be deleterious mutations using SIFT software [14]. The Carolina parakeet transition/transversion ( $\mathrm{Ts} / \mathrm{Tv}$ ) value is 2.309 , the ratio of the non-synonymous to synonymous

Figure 1. Phylogenetic Relationships of the Carolina Parakeet
Calibrated phylogeny built with BEAST2 based on 50 nuclear UCE loci from 18 species of parrots and a passerine (common names in bold). The analysis was constrained to a topology obtained from maximum likelihood analysis of 4,988 nuclear loci ( $9,864,148 \mathrm{bp}$ ), in which all nodes had 100 bootstrap support. Node ages were estimated using two fossil calibrations (highlighted in blue HPD intervals); gray bars indicate $95 \%$ HPD intervals of unconstrained nodes. Clade names follow a recent nomenclature revision [23].
See also Figure S2.
substitutions in all genes ( $\mathrm{dN} / \mathrm{dS}$ ) is 0.48 , and values similar to these have been reported in other bird genomes [15-17].

Sex determination of the specimens is difficult using morphological observations alone, as they have been described as being alike in coloration [4]. Females are the heterogametic sex (ZW) in birds; using genetic data, we were able to conclude that our specimen was a female because it showed about half the average depth coverage on the sex chromosomes (e.g., $13.4 \times$ genome-wide versus $7.11 \times$ at the DMRT1 gene that is located in the Z chromosome).

## Phylogenetic Relationships

In order to investigate the phylogenetic placement of Conuropsis within Psittaciformes and estimate its divergence time, we used 4,988 nuclear loci (ultraconserved elements [UCEs], comprising 9,864,148 bp) extracted from the genomes of C. carolinensis, 17 extant parrots, and the rifleman Acanthisitta chloris (Passeriformes) as an outgroup. Individual gene trees summarized into a coalescent species tree were congruent with concatenated datasets and supported by maximum local posterior probability in all but one node. Gene trees suffered from the few and unusually short loci of one of the samples (Strigops habroptila; 77\% of loci missing and $95.81 \%$ gaps across the concatenated alignment), which resulted in a low supported relationship with Psittacoidea (support $=0.23$ ). This sample was also problematic in coalescent-based analyses in the original study that generated the data [18-21]. Concatenated analyses of all loci and of $95 \%$ and $100 \%$ completeness were congruent and had maximum bootstrap support for Strigops+Nestor as the sister to all other parrots, as found before [18-21]. All other relationships and the placement of Conuropsis were entirely congruent between analyses suppress unambiguous and highly supported. Conuropsis was consistently placed as the sister group of Aratinga, which in turn is sister group to the macaw Ara within Arinae (macaws, conures, and allies) (Figure 1). We also used the complete coding region of the mitochondrial (mtDNA) genome sequence to investigate the placement of Conuropsis against a greater sampling within the Arini and found the same placement as with nuclear data (Figure S2). Molecular clock analysis employing two fossil calibrations [21] suggests that the Aratinga-Conuropsis split occurred around 2.8 mya (1.6-

Figure 2. Demographic History of the Carolina Parakeet
Pairwise sequentially Markovian coalescent (PSMC) plot shows Conuropsis carolinensis population history. We performed 100 bootstrap repetitions. The PSMC plot shows demographic fluctuations of the parakeet population size starting with the beginning of the Last Glacial Period.
See also Figure S3.
4.4; 95\% highest posterior density [HPD] interval) from nuclear genome data and around 3.8 mya (2.73-5.05; 95\% HPD interval) from mtDNA data. Both dates roughly coincide with the widely recognized date of 3 mya for the final closure of the Panama Isthmus [22]. It seems plausible, therefore, that the dispersal to North America occurred after the North and South American landmasses were continuous.

## Demographic History

We used the pairwise sequentially Markovian coalescent (PSMC) algorithm [24] to evaluate the past demographic evolution of Conuropsis and Aratinga species. We found that the Carolina parakeet population experienced an increase in effective population size $\left(\mathrm{N}_{\mathrm{e}}\right)$ during the Middle Pleistocene, followed by demographic fluctuations that started during the Last Glacial Period ( $\sim 110$ kya) and a subsequent population decline that continued until recent times (Figure 2). In contrast, the PSMC of the endangered Aratinga solstitialis shows a stronger and continuous population decline and a longer period of lower effective population size than Conuropsis (Figure S3).

We then profiled both the overall heterozygosity across the genome and the distribution of long runs of homozygosity (RoHs) (Figure S4). The former is a measure of overall genetic diversity, whereas RoHs arise when identical chromosomal fragments are inherited from a recent common ancestor. Thus, significantly reduced heterozygosity is typical of populations that have been small and isolated for long periods, although elevated levels of RoH are usually observed in inbred populations [25]. Both may therefore be typical of endangered species. We found that Conuropsis had a heterozygosity slightly below the average across bird genomes [10] but clearly does not appear to be an outlier (Figure 3) (the low level of heterozygosity of our Aratinga specimen could be influenced by the fact that it was an individual bred in captivity). In addition, 188 total RoHs were detected for Conuropsis ( 9 of them $>1 \mathrm{Mb}$ ), although for Aratinga, the number is much higher ( 611 total RoHs; $85>1$

Figure 3. Genetic Diversity among Birds
Logarithm of the average genome heterozygosity for most published avian genomes. All species belong to different taxonomic orders except for Conuropsis carolinensis and Aratinga solstitialis, which are both Psittaciformes. Samples are colored by IUCN Conservation status.
See also Figure S4.

Mb) (Figure S4). Nevertheless, we report the presence of a single, long run of homozygosity of 7.15 Mb , which is suggestive of recent inbreeding in the ancestors of the Espinelves specimen. It cannot be discarded, in fact, that our specimen was originally bred in captivity. Alternatively, having only a single long RoH could be indicative of some selective sweep in that particular region.

## Adaptation to Toxic Diet

We leveraged our data to explore the genomic basis of a curious behavior of this species, relating to its dietary habits. The Carolina parakeet consumed a variety of fruits, seeds, and to a lesser extent, buds and flowers, but most remarkably, it showed a predilection for cockleburs (Xanthium strumarium). This is unusual, as cockleburs contain significant levels of a diterpenoid glucoside, the carboxyatractyloside or CAT [5], a lethal toxin that inhibits mitochondrial energy production [26]. In a collection of 99 feeding observations of Conuropsis, the highest plant intake $(n=17)$ corresponded in fact to cockleburs [4]. CAT inhibits the function of four mitochondrial ATP transporters (ANT1, ANT2, ANT3, and ANT4; encoded by SLC25A4, SLC25A5, SLC25A6, and SLC25A31, respectively), which is lethal $[26,27]$. We next explored these genes further by

Figure 4. Adaptation to Toxic Diet (A) Mitochondria representation of the outer and inner membrane (zoom in to B).
(B) Cartoon of the bovine ANT protein X-ray crystallographic structure (approximate location of the inhibition by CAT blocking the flux of ATP and ADP + Pi).
(C) Three-dimensional modeled structure of the SLC25A4 in Conuropsis with variable positions of the SLC25A4 in yellow and SLC25A5 in light orange (both modeled protein structures are quite similar-so only one was represented for simplification). The red region of the protein corresponds to the pocket.
(D) Inside view of the 3D modeled structure of the SLC25A4 in Conuropsis (positions labeled as in C). (E) Sequential depiction of the amino acids around the position A122V of SLC25A4 in Conuropsis (comparison bottom-down: human; cow; mouse; opossum; C. carolinensis; A. solstitialis; chicken; anoles; python; green turtle; and crocodile) and indication of the pocket sites (in red) in the protein segment represented.
comparing them against their orthologs in other available avian genomes, including one recently generated dataset representing 363 species spanning nearly all avian families [28]. First, we found that SLC25A6 and SLC25A31 genes are not present in that dataset, presumably due to the annotation pipeline used. We did, however, find that the Conuropsis SLC25A4 and SLC25A5 genes carry two non-synonymous amino acid changes with respect to the Aratinga annotation: A122V in SLC25A4 (a C to T substitution covered by 14 DNA reads) and T126S in SLC25A5 (an A to T substitution covered by 13 DNA reads). An additional variant in this gene, V227A, is shared with 24 other species from different orders. The two SLC25A4 and SLC25A5 substitutions found are conserved in a diverse dataset of vertebrates, in 37 previously published avian genomes [10], and in the newly available avian genome dataset (Figure 4). Among the large avian dataset, additional nonsynonymous substitutions in the four codons preceding and opposite these two positions have only been found in one single species (Pomatorhinus ruficollis). The two sites are located in a helix of the protein and are flanking pocket sites, likely influencing the functionality of both proteins. Therefore, it is possible that these mutations conferred the species with a unique adaptive mechanism for dealing with the toxic CAT present in its diet, although we do not know whether they could be shared with other Aratinga species (besides $A$. solstitialis).

## DISCUSSION

The extinct Carolina parakeet's genome could provide evidence for specific adaptive peculiarities of this species and also help answer questions related to the population history and extinction dynamics of this paradigmatic bird.

Taking advantage of having eighteen available parrot genomes, we have generated the first Psittaciformes genomewide phylogeny, which showed that the divergence time for Conuropsis evolutionary lineage and its subsequent colonization of the North American subcontinent took place around 3 mya. Considering that the time to the most recent common ancestor
of all Psittaciformes is at least ten times larger (about 34.4 mya), we can conclude that the evolutionary history underlying the Carolina-parakeet-specific adaptations is a rather recent process within this order of birds.

We also uncovered evidence of a past population history of expansions and contractions with low effective population size but no dramatic signals of widespread, recent inbreeding that interestingly were discernable in Aratinga. This suggests that, despite the perception of high parakeet abundance based on observations of large and noisy flocks, this species had experienced population contractions that were likely associated to past climatic oscillations. However, scarce evidence of inbreeding indicates that it suffered a very quick extinction process that left no traces in the genomes of the last specimens. In fact, the bird's final extinction was likely accelerated by collectors and trappers when it became evident that it was extremely rare [8].

We found evidence that the Carolina parakeet was adapted to the cocklebur's toxin, but we caution that this feeding behavior is not exclusive of Conuropsis; parrots in general ingest fruits and seeds known to be toxic to other vertebrates [29]. It has been proposed that some species could neutralize them by consuming clay from river banks, which would have a toxin-absorbing function [30], although other physiological detoxification mechanisms cannot be discarded. Nevertheless, it would be interesting in the future to functionally test the two variants detected in the SLC25A4 and SLC25A5 genes using avian cell lines.

Other potential factors for Conuropsis extinction, such as the exposure to poultry pathogens, will likely require a metagenomic screening of at least several parakeet specimens; however, preliminary results from our sample do not show a significant presence of bird viruses.

The potential adaptation to the CAT toxin and the lack of evidence for a dramatic long-term decline and widespread inbreeding suggests that no additional factors contributed to the extinction process. Therefore, the abrupt disappearance of the Carolina parakeet seems to be directly attributable to human pressures.

## STAR $\star$ METHODS

Detailed methods are provided in the online version of this paper and include the following:

- KEY RESOURCES TABLE
- LEAD CONTACT AND MATERIALS AVAILABILITY
- EXPERIMENTAL MODEL AND SUBJECT DETAILS
- Conuropsis carolinensis specimen
- Aratinga solstitialis specimen
- METHOD DETAILS
- Conuropsis DNA extraction and sequencing
- Aratinga solstitialis DNA extraction
- Aratinga solstitialis sequencing and assembly
- Aratinga solstitialis annotation
- Conuropsis carolinensis mapping and variant calling
- Sex determination
- Ultraconserved Elements (UCE) phylogenetic tree

Mitochondrial phylogenetic tree

- Conuropsis population history
- Conuropsis average genome heterozygosity
- Conuropsis Runs of Homozygosity (RoHs)
- QUANTIFICATION AND STATISTICAL ANALYSIS
- DATA AND CODE AVAILABILITY

## SUPPLEMENTAL INFORMATION

Supplemental Information can be found online at https://doi.org/10.1016/j. cub.2019.10.066.

## ACKNOWLEDGMENTS

We are grateful to Arboretum Masjoan (Espinelves, Barcelona) for allowing us to sample the Carolina parakeet of their collection, Antoni Ballester for the radiographic exploration of the specimen, Jordi Grífols and Josep Maria Ramió for the Aratinga sample, and Wen Wang (Kunming Institute of Zoology, Yunnan, China) for his help and advice. The authors acknowledge the Science for Life Laboratory, the Knut and Alice Wallenberg Foundation, the National Genomics Infrastructure funded by the Swedish Research Council, and the Uppsala Multidisciplinary Center for Advanced Computational Science for assistance with sequencing of the Aratinga genome as well as de novo assembly of the data and access to the UPPMAX computational infrastructure. This work was supported by ERC Consolidator Grant 681396 "Extinction Genomics" to M.T.P.G. and M.S.-V., Obra Social "La Caixa" and Secretaria d'Universitats i Recerca (GRC2017-SGR880) to T.M.-B. and C.L.-F., BFU2017-86471-P and PGC2018-101927-B-I00 from MINECO/FEDER, UE to T.M.-B, and PGC2018-095931-B-100 from MINECO/FEDER, UE to C.L.-F. T.M.-B. is also supported by a U01 MH106874 grant and Howard Hughes International Early Career and CERCA Programme (Generalitat de Catalunya). ## LEAD CONTACT AND MATERIALS AVAILABILITY

Further information and requests for resources and reagents should be directed to and will be fulfilled by the Lead Contact, Pere Gelabert (peregelabertx@gmail.com). This study did not generate new unique reagents.

## EXPERIMENTAL MODEL AND SUBJECT DETAILS

## Conuropsis carolinensis specimen

At least 720 skins and 16 Carolina parakeet skeletons are preserved in museum collections globally [65, 66]. We sampled one such specimen with the intention of generating the first near-complete whole genome information of the species. The specimen is preserved in a private collection in the village of Espinelves (Girona, Spain), and was collected at the beginning of the 20th century by the Catalan naturalist Marià Masferrer i Rierola (1856-1923).

The Carolina parakeet is believed to have consisted of two subspecies: Conuropsis carolinensis carolinensis, that was principally distributed in Florida and along the Southeast coast of United States, and Conuropsis carolinensis ludovicianus that was distributed
across the central states of the country [2]. Both subspecies could be differentiated by morphological features such as coloration and body size. The wing, bill, and tail lengths of all adult C. c. Iudovicianus significantly averaged more than in all adult C. c. carolinensis [4]. The wing and tarsal lengths (Figure S1), as well as the general color pattern of the Espinelves specimen, indicate it belongs to C. c. carolinensis.

## Aratinga solstitialis specimen

A sample of blood was obtained in vivo from a female specimen from an official Aratinga breeder.

## METHOD DETAILS

## Conuropsis DNA extraction and sequencing

Two different samples of about 100 mg were obtained, one from the femur (leg bones were preserved inside the naturalized specimen) and one from toepads, with the help of a Dremel machine.

The two samples were digested using 2 mL of extraction buffer containing 10 mM Tris- $\mathrm{HCL}(\mathrm{pH} 8), 10 \mathrm{mM} \mathrm{NaCl}, 5 \mathrm{mM} \mathrm{CaCl}_{2}, 2.5 \mathrm{mM}$ EDTA, $1 \%$ SDS, $1 \%$ Proteinase K and 40 mM DTT. The solution was resuspended by vortexing and was incubated in a rotating plate overnight at $55^{\circ} \mathrm{C}$. Digested samples were purified, and DNA was isolated following a combination of Phenol/Chloroform and column purification, as outlined below.

After incubation, digested samples were centrifuged for 3 min at $3000 \times \mathrm{g}$ and the supernatant was collected and mixed with 1X volume of Phenol. The sample solution was incubated on a rotor for 5 min at RT. After, it was centrifuged for 3 min at $5000 \times \mathrm{g}$ and the upper aqueous layer was collected in new low-bind Eppendorf tube. The collected aqueous layer was mixed with 1X volume of Chloroform and the process was repeated. Again, the upper aqueous layer was collected in new tube and mixed with 10X volume of binding buffer prepared as previously described [67]. The sample solution mixed with the binding buffer was poured into a binding apparatus constructed by fitting an ZymoV extension reservoir in a MinElute column and set inside a 50 mL Falcon tube (as in [68]. Samples were centrifuged at $300 \times \mathrm{g}$ until all the liquid had passed through. The MinElute column was then separated from the reservoir and set into a new 2 ml low-bind collection tube. The column was washed with $730 \mu \mathrm{~L}$ of QIAGEN buffer PE, centrifuged at $3,300 \times \mathrm{g}$, flow-though was discarded and the MinElute column was dry-spun for 1 min at $6000 \times \mathrm{g}$ in a bench-top centrifuge. DNA was eluted in a final volume of $50 \mu \mathrm{~L}$ by adding twice $25 \mu \mathrm{~L}$ of QIAGEN EB buffer and incubating for 5 min at $37^{\circ} \mathrm{C}$ between each elution. Samples were centrifuged at $6000 \times \mathrm{g}$ and extracted DNA was quantified using a Qubit instrument.

Following extraction, $15 \mu \mathrm{~L}$ of DNA extract was built into blunt-end libraries using both the NEBNext DNA Sample Prep Master Mix Set 2 (Cat No. E6070) and the BEST protocol using BGI adapters (as in [11]. Two libraries were built for each method. For the NEB protocol, the libraries were prepared according to manufacturer's instructions, only skipping the initial nebulization step.

The resulting DNA library for each method was then amplified and indexed in 4 PCR reactions of $50 \mu \mathrm{~L}$ each with $16 \mu \mathrm{~L}$ of DNA template on each, mixed with $25 \mu \mathrm{~L} 2 \mathrm{X}$ KAPA U+Buffer, $1.5 \mu \mathrm{~L}$ of BGI amplification primer $(10 \mu \mathrm{M})$ (sequences described in [11]. Thermocycling conditions were 3 min at $98^{\circ} \mathrm{C}$, followed by 22 cycles of 20 s at $98^{\circ} \mathrm{C}, 30 \mathrm{~s}$ at $60^{\circ} \mathrm{C}$ and 30 s at $72^{\circ} \mathrm{C}$, and a final 7 min elongation step at $72^{\circ} \mathrm{C}$. The amplified library was purified with PB buffer on QIAGEN MinElute columns, before being eluted in $30 \mu$ L EB. Negative library controls, constructed with $\mathrm{H}_{2} \mathrm{O}$, were included, as well as libraries constructed on the negative extraction controls; both subsequently yielded no DNA sequences.

Amplified libraries were quantified using a TapeStation instrument (Agilent) and two sequencing pools were created by merging the amplified libraries for each method and sequenced on 2 lanes of a BGISEQ-500 sequencing instrument using 100SR chemistry. Libraries prepared from tibia bone powder exhibited longer DNA reads in comparison with the toe tissue ( $\mathrm{x}=83 \mathrm{bp}$ versus $\mathrm{x}=61 \mathrm{bp}$, $p<0.001$ ). NEB libraries yielded longer DNA reads than BEST libraries ( $x=84.86$ and $x=63.45$ versus $x=75.39$ and $x=60.31$ in tibia and toe respectively, $p<0.001$ ). NEB libraries were also the ones that yielded higher endogenous DNA content as well as lower clonality.

## Aratinga solstitialis DNA extraction

Parallel genomic DNA extractions were performed on blood from a single Aratinga solstitialis female individual using the DNeasy Blood \& Tissue Kit (QIAGEN, Valencia, CA) following manufacturer's instructions. The resulting DNA extracts were quantified using the Qubit 2.0 Fluorometer (Thermo Fisher Scientific, Waltham, MA) with no modification of its standard protocol. To check for molecular integrity, each DNA extract was run on the 2200 TapeStation (Agilent Technologies, Santa Clara, CA) following manufacturer's protocol.

## Aratinga solstitialis sequencing and assembly

Using the high molecular weight (HMW) DNA extracts, a short PCR-free insert library with 180 bp inserts was prepared using TruSeq DNA kit (Illumina, CA, USA) according to the manufacturer's instructions. In addition, three different mate-pair libraries were built using the Nextera protocol (Illumina, CA, USA). These comprised one 3 kb mate-pair library, one 5 kb mate-pair library, and one 20kb mate-pair library. All libraries were indexed to enable de-multiplexing after sequencing. The libraries were subsequently sequenced on the Illumina HiSeq X platform (using $2 \times 150$ bp reads), where the first lane was used for the 180 bp insert library. For the second lane, the three mate-pair libraries were pooled in equimolar ratios prior to sequencing.

In order to generate a de novo assembly, three different assemblers were used: ALLPATHS-LG v.52485, ABySS v.1.3.5 and SOAPdenovo. Out of the three assemblers, ALLPATHS-LG gave the best result, with an N50 scaffold measure of 19.5Mbp.

## Aratinga solstitialis annotation

We used a homology-based method to annotate the protein-coding genes in the Aratinga genomes by using Ensembl gene sets (release 85) of chicken (Gallus gallus), zebra finch (Taeniopygia guttata) and human (Homo sapiens), and genes derived from published avian transcriptomes. The protein sequences of the reference gene set compiled above were used as references for homol-ogy-based gene prediction.

We aligned reference protein sequences to the genome by TBLASTN with an E-value cut-off of $1 \mathrm{e}-5$. We linked the hits into candidate gene loci with genBlastA and removed candidate loci with a homologous block length shorter than $30 \%$ of length of query protein. We extracted genomic sequences of candidate gene loci and 2,000bp upstream/downstream sequences as input for GeneWise to predict gene models in the genome. Then we translated the predicted coding regions into protein sequences, and ran MUSCLE for each pair of predicted protein and reference protein. We filtered out the predicted proteins with length of < 30aa or percent identity $<40 \%$, as well as the pseudogenes (genes containing $>2$ frameshifts or pre-mature stop codons) and retrogenes. The output of GeneWise could include redundant gene models, which overlap at the same genome regions. Hierarchical clustering was applied to the output of GeneWise to build a non-redundant gene set. Genes that overlapped in $>40 \%$ of their coding sequence were clustered and kept the sequence with the highest identity to the reference genes. We removed the highly duplicated genes (frequency of duplications $>10$ ) in two conditions: 1) with a single exon; 2) with $>70 \%$ repeat sequences in coding region.

## Conuropsis carolinensis mapping and variant calling

The ancient DNA reads were clipped using cutadapt; sequencing adapters were removed. Only reads longer than 30bp were kept. Filtered reads were mapped against the A. solstitialis assembly with Burrows-Wheeler Aligner (BWA) [69], setting no trimming, disabling seed, increasing stringency for edit distance, and allowing opening of 2 gaps. Duplicated reads were removed using Pic-ard-tools MarkDuplicates. Mapped reads with mapping quality below 30 were removed using Samtools. The resulting reads were examined with mapdamage2 to assess the degradation rate of the data, which is a sign of authenticity. We detected the presence of typical aDNA-damaged bases at the end of reads. To avoid problems in the next steps, we trimmed 2 nt from each read end using BamUtil trimbam.

Genotypes were estimated using GATK UnifiedGenotyper. We removed calls with base quality below 30 (-mbq), and we set the rest of parameters as default. The average depth of coverage of the sample was 13.4 X . To prevent variant calling errors in repetitive or complex regions, we used GATK SelectVariants to exclude the calls with depths of coverage below 10x and above 35X. Afterward we also used GATK SelectVariants and GATK FilterVariants to exclude from the call-set InDels and heterozygous calls in allele frequencies below 0.2 and above 0.8 . We subsequently used the $A$. solstitialis assembly annotations to build a SNPeff database and used Gallus annotations to determine derived alleles.

## Sex determination

The Aratinga genome -which we knew was a female-showed, as expected, half of coverage in the ZW chromosomes [70]. We plotted the depth of coverage distribution for each scaffold of the Carolina parakeet using Samtools and found identical coverage distribution. We subsequently searched for the DMRT1 gene [71] to confirm the Aratinga Z chromosome scaffold.

## Ultraconserved Elements (UCE) phylogenetic tree

For phylogenetic analysis, we targeted 5,060 UCE loci from 14 species with whole genome sequences (including the two new genomes presented here) and from 5 parrots that were included in a previous UCE capture study [21]. The Tetrapods-UCE-5Kv1 bait set [72] was applied to 18 parrots and the outgroup Acanthisitta chloris. A total of 4,988 UCE sequences were identified and extracted with the flanking 1000bp to both sides, aligned and trimmed using PHYLUCE (commands in 10.17632/p4wt7jc9dw.1). Strigops habroptila from the targeted capture study had significantly fewer and shorter loci than all other samples (1,648 loci, 269bp length on average compared to 757bp on average across samples from [21]) but we kept the sample because of its significance for fossil calibration.

We used coalescent and concatenation approaches to infer phylogenetic relationships. First, we constructed maximum likelihood gene trees for all 4988 alignments using IQTREE with 1000 ultrafast bootstrap replicates after determining the most appropriate nucleotide substitution model with ModelFinder. The resulting gene trees were summarized into a coalescence-based species tree using ASTRAL-III. Second, we concatenated all loci ( $9,864,148 \mathrm{bp}$ ), the 2,755 loci that were present in $95 \%$ of all species ( $5,561,275 \mathrm{bp}$ ) and the 893 loci that were present in $100 \%$ species ( $1,840,245 \mathrm{bp}$ ) and analyzed them as above.

For calibration analyses, we drew two random samples of 50 loci that had all taxa and had the same substitution model (HKY+ F+G4, the most common model across all loci). For both random samples, we executed two MCMC chains ( 100 million generations, sampled every 5,000 generations) in BEAST2 on the CIPRES Science Gateway [73]. Each analysis was performed on the topology from concatenation, employing a birth-death model, a relaxed clock model with lognormal distribution on the rate prior and HKY+ F+G4 as the substitution model. The age of two nodes was constrained with lognormal distributions following the thorough published fossil justifications [21]. First, a lognormal prior was placed on the root of the tree (Passeriformes+Psittaciformes, Eozygodactylus americanus) with an offset of 51.81 Mya and a $97.5 \%$ quantile encompassing 66.5 Mya. Second, a lognormal prior was placed on
the MRCA of Strigops + Nestor (Nelepsittacus minimus) with an offset of 15.9 Mya and a $97.5 \%$ quantile at 66.5 Mya. Replicate runs were checked for convergence in Tracer, combined and annotated after a burning of $30 \%$ with LogCombiner and TreeAnnotator.

## Mitochondrial phylogenetic tree

Trimmed DNA reads $(209,887,920)$ were mapped against A. solstitialis mtDNA genome (JX441869). The mtDNA consensus sequence of Conuropsis was obtained by using schmutzi endoCaller and aligned with Clustal Omega to 11 other Arini mtDNA genomes and Amazona ventralis as outgroup. The obtained alignment of 13 sequences of $18,731 \mathrm{bp}$ in total length was dated using BEAST based on a fixed clock rate of 0.0042 substitutions/site/MY for all coding regions, which was previously determined for the brown-throated Parakeet Eupsittula (formerly Aratinga) pertinax [74]. The number of polymorphic sites of Conuropsis mtDNA genome in the alignment was 4,369 . We used the GTR $+1+G$ nucleotide substitution model selected by jModelTest with the Akaike Information Criterion.

## Conuropsis population history

We used the Pairwise Sequentially Markovian Coalescent (PSMC) model to explore the demographic history of $C$. carolinensis. We obtained a fastq sequence of $C$. carolinensis for autosomal regions in scaffolds longer than 100Kbps. Only positions with a depth of coverage above 8 X and below 50X were kept. Posteriorly a PSMC was built using the following parameters: -N25, -t15, -r5, -p " $4+25^{*} 2+4+6$." We used age of sexual maturity ( 1 year) [3], multiplied by a factor of two as a proxy for generation time, following the same approach as in a previous study of PSMC in 38 avian species [52] and a mutation rate of $2.3 \times 10^{-9}$, estimated from bird pedigree information [75].

## Conuropsis average genome heterozygosity

To identify regions of the $C$. carolinensis genome that shows signs of homozygosity we plotted the distribution of heterozygous positions across the genome sequence. We examined the scaffolds counting the number of heterozygous positions in windows of 50 Kb with 10 Kb of overlap. We define the average genome heterozygosity as the proportion of heterozygous sites genomewide divided by the total number of callable bases. We kept only SNV sites applying the following filtering criteria: Read Depth >10, Genotype Quality > 20, Allele Balance $0.2<\mathrm{AB}<0.8$ (hypergeometric distribution 0.95 Cl [ $0.233-0.766]$ ]. All variable repeats, indels and multiallelic sites were removed. Non-variable sites were considered callable if their read depth was larger than 10. Additional heterozygosity values for other bird species were extracted from published avian genomes [10].

## Conuropsis Runs of Homozygosity (RoHs)

RoHs were called based on the density of heterozygous sites in the genome using a Hidden Markov Model (HMM) for segmentation: First, the Aratinga reference genome was partitioned into 50 Kb windows guided by the Conuropsis callability mask, namely, uncallable Conuropsis sites were omitted in the window tally. Heterozygosity values were calculated for each window as described above. Next, an HMM (python3 pomegrenate package) was fitted to the data. Emissions were modeled based on the empirical window heterozygosity distribution with a two/three component Gaussian Mixture Model (GMM). The first component of the GMM was reserved to extremely small heterozygosity values in order to capture the RoH variability, while the second component was allowed to vary freely. If necessary, a third mixture component was added to capture outliers. The transition probabilities were trained using the Baum-Welch algorithm.

## QUANTIFICATION AND STATISTICAL ANALYSIS

All statistical details of experiments can be found at the STAR Methods. The phylogenetic tree in Figure 1 was performed with BEAST 2 (https://www.beast2.org). The pattern of post-mortem damage in Figure S1 was generated with mapdamage2 and the contamination estimates at the mtDNA was done with Schmutzi program. Adaptors from the DNA reads were removed with cutadapt. Genetic differences between Conuropsis and Aratinga were explored with SIFT software and the prediction of effects of some polymorphisms was done with SNPeff software.

## DATA AND CODE AVAILABILITY

The accession numbers for the Conuropsis and Aratinga genomes reported in this paper are in the European Nucleotide Archive (ENA): PRJEB33130 and PRJEB33153, respectively.

## Supplemental Information

## Evolutionary History, Genomic Adaptation to Toxic Diet, and Extinction of the Carolina Parakeet

Pere Gelabert, Marcela Sandoval-Velasco, Aitor Serres, Marc de Manuel, Pere Renom, Ashot Margaryan, Josefin Stiller, Toni de-Dios, Qi Fang, Shaohong Feng, Santi Mañosa, George Pacheco, Manuel Ferrando-Bernal, Guolin Shi, Fei Hao, Xianqing Chen, Bent Petersen, Remi-André Olsen, Arcadi Navarro, Yuan Deng, Love Dalén, Tomàs Marquès-Bonet, Guojie Zhang, Agostinho Antunes, M. Thomas P. Gilbert, and Carles Lalueza-Fox

Figure S1: Morphological and post-mortem DNA damage analysis. Related to the STAR Methods. Above left: tarsal measurements of the Espinelves female studied compared with average and range measurements for adult females from the literature [S1]; the values indicate the specimen belongs to Conuropsis carolinensis carolinensis subspecies. Above right: X-ray image used to measure the tarsal bones. Below: nucleotide deamination pattern at the end of the Carolina parakeet reads, deriving from cytosine deamination in ancient sequences [S2]. The ratio (about 4-5\% of the reads) is consistent with the age of the sample.

Figure S2: Calibrated phylogeny built with BEAST based on mitochondrial genomes of 13 species of Neotropical parrots. Related to Figure 1. A 0.0042 substitutions/site/MY molecular rate was used to calibrate the phylogeny. 95\% HPD intervals are shown in the nodes in addition to bootstrap values below 1. The Aratinga-Conuropsis split occurred around 3.8 Mya.

Figure S3: Pairwise Sequentially Markovian Coalescent (PSMC) plot of Aratinga solstitialis population history. Related to Figure 2. We performed 100 bootstrap repetitions.

Figure S4: Heterozygosity across scaffolds (vertical doted lines represent contigs in the scaffold) and histogram of Runs of Homozygosity (RoH). Related to Figure 4. Length count for Conuropsis carolinensis (above) and Aratinga solstitialis (below), at the same scale. Only one long RoH of $>7 \mathrm{Mb}$ was observed in the former species.
